While genetic markers play an important role, alcohol biomarkers are physiological indicators of alcohol exposure or consumption,. Their clinical detection often reflects acute, chronic, and/or a high level of alcohol exposure. Current alcohol biomarkers generally fall into two types: direct and indirect biomarkers.

Background: Biomarkers of alcohol consumption are important not only in forensic contexts, e.g., in child custody proceedings or as documentation of alcohol abstinence after temporary confiscation of a driver's license. They are increasingly being used in clinical medicine as well for verification of abstinence or to rule out the harmful use of alcohol.

Alcohol Biomarkers in Clinical and Forensic Contexts

Direct alcohol biomarkers, such as the detection of ethanol in the serum, urine, breath, or bodily fluids, are considered to be the gold standard in alcohol detection. However, because alcohol is rapidly cleared from the body, these biomarkers are valid only to test for recent alcohol intake.

Biomarkers for monitoring alcohol use

Finally, although often used as screens for diagnosis of alcohol abuse or dependence, strictly speaking, biomarkers are reflections of physiological reactions to heavy drinking. Self-report screening scales, on the other hand, generally use a diagnosis of alcohol dependence as the criterion against which they are evaluated.

Biomarkers of Heavy Drinking

Clinical Biomarkers of Alcohol Use There are a number of potential aspects of alcohol abuse and alcohol-induced tissue damage that biomarkers could be used to diagnose. These can be broadly defined as indicators of cumulative intake over a given time period, drinking patterns, and alcohol-induced organ damage.

Carbohydrate-deficient transferrin (CDT) is a glycoform profile of serum transferrin that increases in response to sustained high alcohol intake and over the last decades has become an important alcohol biomarker with clinical and forensic applications.

Clinicians can use several biochemical measurements to objectively assess patients' current or past alcohol use. However, none of these currently available biomarkers—including measures of various liver enzymes and blood volume—are ideal. Several more experimental markers hold promise for measuring acute alcohol consumption and relapse.

To improve understanding of this issue, researchers have measured cardiac specific biomarkers in the blood of adults with no history of heart disease, and correlated the results with alcohol consumption. The September 2016 issue of Clinical Chemistry details this study. The article's primary author, Dr. Mariana Lazo, joins us for this podcast.

Self-reports of alcohol use—such as CAGE and the Alcohol Use Disorders Identification Test (AUDIT)—are valid, inexpensive, and noninvasive, but patients easily can feign results. 1 Biochemical measures are more objective, and combinations of markers are an effective tool to detect recent heavy drinking in the 10% to 25% of patients who underreport alcohol use. 2

Clinical experience suggests that alcoholics are more susceptible to liver injury by paracetamol, supported experimentally using a pair-fe eding model of alcohol administration. Finally, chronic alcohol consumption upregulates CYP 2E1, stimulating the microsomal metabolism of paracetamol and ethanol.

Introduction. Alcohol consumption has been shown in numerous epidemiologic studies to be associated with a small increase in the risk of invasive breast cancer (1-6).Meta-analyses indicate that the risk of breast cancer increases linearly with increasing alcohol intake, with an approximately 10% increase in risk for each 10 g/d increment of ethanol (1, 3, 4), although some studies suggest that ...
